Horn flies are small (3/16 inch long), dark gray flies that feed on cattle and occasionally horses. Both sexes are blood feeders, taking 20 or more blood meals each day with their stiff needle-like mouthparts. Irritations from the bites annoy animals and occasionally, the wounds may become infected.

Studies have shown that horn flies have their greatest effect on growing animals. Weaning weights of calves with an average of 200 or more horn flies during the summer are about 15 pounds less than those that are protected from horn flies. The same type of impact has been seen on yearling cattle. In addition, horn flies can spread summer mastitis, which affects the mammary glands of non-lactating cows, and they have been implicated in the spread of anaplasmosis.

Several insecticide application options are available: insecticide impregnated ear tags, dust bags, concentrated pour-ons, animal sprays, and oral larvicides available in minerals and feed supplements. Ear tags and forced use dust bags have consistently given the best control but other methods can be effective, too. The choice can be made based on what works best with pasture layouts and herd management practices.

Insecticide resistance has become a problem, particularly associated with the use of insecticide ear tags and continued use of insecticides with the same mode of action – attacking the same site in the insect. Specific steps can be taken to manage resistance, including: 1) rotation of insecticides in ear tags with different modes of action, 2) withholding tagging until horn fly numbers reach 200 per animal, 3) only treating cattle in the growth mode, 4) use of alternative insecticides and application methods late in the season to reduce the percentage of overwintering flies with resistance; and 5) removing insecticide ear tag as soon as horn fly numbers begin to decline in the fall.

Several species of predator beetles feed on horn fly eggs and maggots in cattle droppings and may reduce horn fly production by more than 90%. Wasps sold for fly control around stables and feedlots are impractical for pasture pests, such as the horn fly. Conditions that fast drying of manure, along with activities of dung beetles also can provide some natural control.

A walk-thru fly trap has been shown to reduce horn fly numbers. Information on this approach is available in Univ. of Missouri publication G1195 - Walk-Through Trap to Control Horn Flies on Cattle.
